Dermoid, Epidermoid, Cysts, Lipoma

Dermoid, Epidermoid, and Neuenteric Cysts
- Benign dysraphic malformations (dysembryogeneses) at GASTRULATION stage* of development
  - traditionally, such disorders have been described as primary failure of NEURULATION (later stage in embryogenesis than gastrulation)  
  - primary disruption of tissues derived from one or more of three germ cell layers:  
    - DERMED AND EPIDERMED CYSTS - DERMAL SINUS TRACTS - surface ectoderm malformation.  
    - NEUENTERIC CYSTS - endodermal malformation.  
    - frequently associated with mesodermal malformations (esp. vertebrae - hernivertebrate, absent vertebrae, fused vertebrae, butterfly vertebrae, midline bony spurs).  
    - cysts manifest in patients of any age.  
    - clinically onset is usually insidious; occasionally cyst rupture and spillage of irritative contents into subarachnoid space → acute meningeal complaints or increased ICP.  
  - treatment of each of these entities is primarily surgical; radiotherapy and chemotherapy have little to offer.

Neuenteric Canal - normal embryologic transitory communication between neural tube FETOTERGUM, DERMED CYST, and gut ENDODERM; canal persistence → paravertebral neuenteric cyst(s) or fistula(s).

by third embryonic week, this neuenteric canal closes, and notochord separates from primitive gut.

develop as early as embryonic day 16-17 - part of split notochord syndrome or split cord malformation.

do no definite sex predilection (spinal neuenteric cysts more often in males, whereas 60% of intracranial cysts have been reported in females).

0.7-1.3% of all spinal cord tumors.

spinal neuenteric cysts are almost pathognomonically associated with vertebral anomalies or diastematomyelia.

5% of patients with Klippel-Feil syndrome and vertebral fusion abnormalities may have neuenteric cysts and fistulas.

Neuenteric Cyst

(4. enterogenous cysts, neuroepithelial cysts, gastrocytomas, foregut cysts)

Pathology
- benign slow-growing cysts
- loculated (intra and extra axial):
  - A. Most commonly - spinal canal (particularly in low cervical or high thoracic region; can be found both ventral and dorsal to spinal cord, as well as in intramedullary location.
  - Intracanal (most often posterior fossa - postomedullary region, cerebellomedullary angle, paravascular area, and craniovascular junction)
  - N.B. most are VENTRAL and EXTRA-CANAL.
  - cyst wall is composed of well-differentiated cuboidal, columnar, or ciliated epithelium, with or without goblet cells or microvilli. mucin-containing cells show positive reaction with periodic acid-Schiff stain and are seen in 75% to 80% of specimens.
  - epithelium may resemble intestinal or respiratory type, and there may be smooth muscle in underlying fibrous vascular tissue.
  - cyst fluid - clear and colorless, milky, yellowish, gelatinous, xanthochromic, and blackish and viscous.
  - immunohistochemical staining - positive for cytokeratin and epithelial membrane antigen and negative for vimentin, glial fibrillary acidic protein, and S-100.
  - cells also often test positive for carcinoembryonic antigen (CEA).
  - differentiate between neuenteric* and ependymal cysts.

*presence of underlying basement membrane or collagenous tissue separating epithelial layer from neural tissue → lack of immunoreactivity to GFAP, S-100, neuron-specific enolase, and vimentin.

malignant transformation is rare.

Clinical Findings
- slow and insidious compression of adjacent spinal cord
- persistent fistulas (between enteric structures and these cysts within CNS) → recurrent aseptic meningitis.

Imaging
- Differential - from simple arachnoid cysts to complex teratomas.
- MRI - variable and heterogeneous cyst signal (often parallel signal intensity of CSF), no enhancement (some variable wall enhancement may be present)
  - reports of T1 signal changes in these tumors, resulting from changes in protein concentration or hemorrhage.
  - cysts have tendency to insinuate themselves between surrounding structures.
- A. T1-MRI - hypointense suprarefluar mass.
- B. Hypointense midline suprarefluar lesion.
- C. T1-MRI - cystic lesion.
- D. Contrast-enhanced, T1-MRI - rim of cyst wall enhancement and region of intracyst enhancement.
- E. T2-MRI - hypointense signal of cyst contents that follows signal change in cerebrospinal fluid.
- F. FLAIR MRI - increased intensity in cyst and some parenchymal hyperintensity around tumor, consistent with edema.
- G. Perinatal density axial MRI - cyst contents somewhat heterogeneous.
- H. Gradient echo axial MRI - cyst heterogeneity.

Last updated: September 5, 2017

*NEUENTERIC CYST...
TREATMENT

- primarily surgical - complete resection (not always feasible given difficulty of completely removing cyst wall at locations where it adheres to adjacent structures)

  * simple cyst aspiration, cyst wall marsupialization, or creation of cyst-subarachnoid shunt, are considered in difficult cases.

  * aseptic meningitis has not been problem one might expect.

  * recurrence is possible even after gross total resection → reoperation.

  * radiotherapy and chemotherapy have little to offer; whether there may be some role for radiosurgery in treatment of residual neurenteric cysts remains to be seen.

DERMOID tumor, EPIDERMOID tumor - benign inclusion cysts (not true neoplasms!) composed of ectodermal elements.

dif. CHOLESTEATOMA → see p. Ear38

ETIOLOGY - congenital (embryonic remnants) - inclusion of ectodermal epithelial elements:

  a) during 3-5th embryonic weeks when neural tube closes at midline → midline tumors (esp. DERMIDS)

  b) during formation of secondary cerebral vesicles → lateral tumors (esp. EPIDERMOIDS).

N.B. EPIDERMOIDS also may be acquired – due to trauma, frequently from lumbar puncture (epithelial cells deposited within spinal canal, mostly historical when spinal needles didn’t have stylet).

PATHOLOGY - similar appearances and developmental origins;

  - both contain stratified squamous epithelium found in skin.

  - centrally, both contain desquamated epithelial keratin and some lipid material (cyst fluid may contain cholesterol crystals).

  - external surface is smooth, lobulated; EPIDERMOIDS has pearly appearance ("pearly tumors" or "keratin pearls" in wall due to capsule of stratified squamous epithelium.

  * histo - cell nuclei among keratin (vs. pure keratin s. "wet keratin" in craniopharyngioma)

EPIDERMOIDS have outer connective tissue capsule and are lined with stratified squamous epithelium (i.e. composed of ectodermal remnants).

DERMOIDS have outer connective tissue capsule and are lined with stratified squamous epithelium, which also contains hair follicles, sebaceous glands, and sweat glands (i.e. composed of ectodermal and mesodermal remnants).

  vs. TERATOMAS - composed of ectoderm, mesoderm, and endoderm

- expand slowly over many years due to central accumulation of epithelial debris and glandular secretions – predictable linear growth due to accumulation of keratin (vs. tumors – grow exponentially due to cell multiplication).

  - dermoids frequently calcify; epidermoids calcify uncommonly (but when it occurs, it is feature that helps in distinguishing from arachnoid cysts).

  - malignant transformation is rare.

LOCATION - sites of epithelial deposition can occur anywhere between neural tube and overlying skin surface (depending on stage of intrauterine development at which they arise, they can lie within ventricular system, brain parenchyma, subarachnoid space, bones of skull, or even extracranially).
**EPIDERMOID**

- Uncommon (0.5-0.3% of all brain tumors).

**EPIDERMOID** - 4-10 times more frequent than dermoid (≈ 2% of all intracranial tumors).

**CLINICAL FEATURES**

**Patient's age at diagnosis:**
- **Dermoid:** Generally do not produce clinical symptoms until 2nd decade of life (i.e. > 20 yrs).
- **Epidermoid:** Enlarges more slowly than dermoid. - 40-50 yrs.

**Symptoms & signs** are associated with slowly progressing mass/pressure effect (seizures, diabetes insipidus, hypopituitarism, etc.).
- Blockage of CSF flow only rarely!
- Cyst rupture → giant granulomatous chemical meningitis (rarely results in infarction from vasospasm).

**Associated dermal sinus tracts / dimples are common:**
- Any infant with dermal sinus tract → neuroradiological evaluation!
- Congenital lumbar dermal sinus may terminate in **epidermoid** (less frequently **dermoid**) within or near conus medullaris or cauda equina; often associated with spinal dysraphism and vertebral abnormalities.
- Congenital nasal dermal sinus may be associated with **dermoid** or **epidermoid**.
- If associated dermal sinus tract becomes infected → recurrent bacterial meningitis.

**DIAGNOSIS**

- **Absence of edema** is characteristic!

**Plain radiographs** – local bone expansion or erosion, lytic lesions with thin sclerotic margin.

**CT**: Well-circumscribed, unilocular cystic mass; calcifications in tumor wall.
- Contrast enhancement is uncommon!! (**epidermoid** wall may sometimes enhance).

**Dermoid** frequent, gives very low density (may be slightly heterogeneous due to additional extramedullary elements - hair follicles, sebaceous glands, sweat glands).

**Fat fluid level** in ventricles or fat droplets in subarachnoid spaces strongly suggest **dermoid** rupture.

**MRI**: Dermoid - characteristics similar to fat (glandular secretions) – midline mass intensely on both T1 and T2 – unique tumor!
- Chemical shift artifact is often present on T2 images as markedly hypointense band posterior at fat fluid interface.

**Epidermoid** - characteristics similar to CSF – variably hypointense on T1 and variably hyperintense on T2 – mimics arachnoid cyst (H: DWI – epidermoid has diffusion restriction).

**Angiography** - avascular mass.

Prenatal diagnosis with ultrasound (and resection shortly after birth) are now possible.

**Suprasellar dermoid**

- **A**: Non-contrast T1 weight with saturation - high signal intensity suprasellar mass extending along planum sphenoidale.
- **B**: Contrast T1 with fat saturation - small amount of enhancement along peripherally aspects of lesion (arrows); majority of mass suppresses with fat saturation.

**Dermoid** (nonenhanced CT): Well-circumscribed, cystic, low-attenuating lesion at midline in suprasellar region; posterior to 3rd ventricle; small focus of calcification noted at posterior margin of tumor.

**Epidermoid** (enhanced CT): Hyperintense lesion; crescentic posterior rim of hyperintensity represents fat chemical shift artifact.

**Intradural extramedullary** = 50% intradural extramedullary = 50% extradural = less common.

**Dermoid** should be considered whenever lumbar puncture yields fat in CSF.

**Epidermoid** - most commonly lateral near cerebellopontine angle; may also occur in suprasellar and parasellar regions, chondral, sylvian, and interhemispheric fissures, intraventricular, intradiploic (in cranial bones), inside spinal cord; intracerebral epidermoid is very rare.
Dermoid, Epidermoid, Cysts, Lipoma

**Dermoid**: (nonenhanced CT) - large, well-circumscribed low-attenuating cystic lesion in right temporal lobe lateral to cranial midline; peripheral marginal calcification; no erosion in adjacent bone of sella.

Same dermoid (contrast CT) - partial marginal enhancement; attenuation degree in center of lesion consistent with fat.

Same dermoid (T1) - hyperintense signal in lesion; multiple small hyperintense foci along sulci of right temporal lobe (represent fat droplets in subarachnoid space from focal dermoid rupture).

Same dermoid (T1 with contrast) - hyperintense lesion (hyperintensity is due to short T1 of fat); multiple hyperintense foci (fat droplets) in subarachnoid spaces; mild midline septal shift to left; chemical-shift artifact at superior marginal surface of lesion.

**Epidermoid** (T1 with contrast) - suprasellar, prepontine, and interpeduncular location of nonenhancing tumor (signal intensity similar to CSF): Epidermoid (A-T2 weighted; B-T1 weighted MRI): left Sylvian fissure is filled by mass which extends into chiasmatic cistern and encases left internal carotid artery termination (arrowhead); signal is similar to CSF on T2, but slightly higher than CSF on T1 (color artefact).

Epidermoid: A. T2-MRI – large homogeneous mass, which is slightly higher in signal than CSF, fills right cerebellopontine angle B. T1-MRI – lesion is again noted to be hyperintense to cerebrospinal fluid.

**TREATMENT** - complete surgical excision is curative.  
- epidermoids do not invade but interdigitate around vital structures - complicating surgical removal.  
- avoid spilling of contents (→ chemical meningitis).  
- associated dermal sinus should be removed completely.

Chemotherapy and radiotherapy are not useful.

**EPIDERMOID CYSTS** (from WHO manual) - benign ectopic inclusions of epithelial cells during gastrulation (i.e. malformations of surface ectoderm) → secondary disruption of neural tube closure (i.e. dysraphism is secondary).

N.B. epidermoid and dermoid cysts represent malformations of surface ectoderm (as opposed to neuroectoderm)

**PATHOLOGY**  
- location - tend to be off midline:  
  A. SPINE - intradural extramedullary (rarely intramedullary)  
  B. CRANIAL (0.2% to 1.8% of all intracranial tumors)  
    a) intradural (usually extra-axial) - cerebellopontine angle (may extend into Meckel's cave) or parasellars cisterns  
    b) extradural (usually arising in diploic space of calvaria)  
- thin capsule of stratified, keratinized squamous epithelium.  
- cyst contains accumulation of desquamated epithelial cells, keratin, and cholesterol (characteristic pearly flakes).  
- malignant transformation is rare, but SQUAMOUS CELL CARCINOMA has been reported (reported 15 cases with leptomeningeal dissemination of squamous cell carcinoma); MALIGNANT MELANOMA has also been reported in temporal lobe epidermoid.

- immunohistochemical staining positive for carbohydrate antigen CA19-9* (also detected in serum - can be used to evaluate for tumor recurrence or progression).

* tumor marker for pancreatic cancer
CLINICAL FINDINGS
- reported from infancy to adulthood + incidental findings at autopsy.
- average age at detection is 35-40 years
- female predominance
- grow linearly (similar to normal skin) → insidious onset (median duration of symptoms 4-14 years).
- picture of acute meningitis may indicate epidermoid cyst rupture.
- spinal epidermoid tumors are frequently associated with vertebral anomalies.

EXTRADURAL LESIONS - manifest as focal mass.
INTRADURAL TUMORS - headache (because of common parasellar location), visual disturbance, and to lesser extent, hypothalamic alterations.
- tumors in middle fossa grow quite insidiously and are often asymptomatic.
- tumors in cerebellopontine angle may cause ataxia, dizziness, or cranial nerve deficits.

IMAGING
CRANIAL XR - for intradiploic tumors - typically in cranial vault (may also occur in orbital region)
- lytic erosion of skull, sharply delineated sclerotic edge and scalloped margins on plain radiographs.
- inner table of skull is usually destroyed and outer table thinned.

CT - homogeneous nonenhancing hypodense lesion in subarachnoid space without surrounding edema.
- occasionally, high density masses (“white epidermoids”) - difficult diagnosis.

Differential diagnosis: arachnoid cyst, Rathke’s cleft cyst, craniopharyngioma.
- differentiation from ARACHNOID CYST:
  1) diffusion restriction on DWI (vs. arachnoid cysts – no diffusion restriction)
  2) more fat density than CSF density
  3) extend into subarachnoid space and enlarge it (vs. arachnoid cysts cause more focal mass effect).

MRI - hypointense to hypointense, heterogeneous, multiloculated.
- T1 hypointensity + T2 hyperintensity
- some tumors show rim enhancement
- no surrounding edema
- hydrocephalus is rare
- DW imaging is superior to other types of MRI sequencing in delineating borders of epidermoid cysts.

A. Contrast-enhanced, T1-MRI - hypointense mass without enhancing components in midline posterior fossa. The mass is compressing brainstem and obstructing egress of cerebrospinal fluid from fourth ventricle, thereby causing hydrocephalus.
B. More lateral extent of this tumor.
C. Mass insinuating between normal posterior fossa structures and extending to involve both right cerebellopontine angle and midline structures.
D. Contrast-enhanced, FLAIR MRI - marked heterogeneity within cyst and discontinuous rim of cyst wall enhancement.

TREATMENT
- symptomatic patients benefit from surgery (technically difficult because of tumor adhesions)
- tumor is well demarcated, with smooth, hypovascular capsule
- primary intracapsular debulking (CUSA is extremely useful) → removal of capsule (fragments of capsule adherent to important structures are left when necessary to avoid neural or vascular injury).
  - although subtotal resection increases risk for recurrence, slow growth of epidermoid cysts makes this less problematic.
  - capsule should not be removed from intramedullary cysts because risk of causing neurological deficits or prooperative cyst rupture (radiographic finding of small fat globules in subarachnoid and intraventricular spaces)
- MENINGITIS → steroids
- no established role for radiotherapy or chemotherapy for residual / recurrent epidermoid cysts.

DERMOID CYSTS (from WHO manual)
- manifest at earlier age than epidermoids and have shorter duration of symptoms (duration of symptoms average 8.5 years; vs. 16 in epidermoids).
- female predominance
- denser tumors than epidermoids → more focal mass effect - patients are initially seen at younger age (average age at diagnosis - 15 years; vs. 35-40 in epidermoids).
- tend to occur at MIDSUNE (when extradural, may arise at anterior fontanelle).
- reported in association with Klippel-Feil syndrome.
**PATHOLOGY**

- positive for CA19-9 in many cases (serum CA19-9 levels tend to be higher than in epidermoid cysts - means of follow-up for residual or recurrent disease).
- tumor marker for pancreatic cancer
- dermoids contain elements of dermis (hair and hair follicles + apocrine, sebaceous, or sweat glands)
- epithelial cell lining may be less differentiated (than in epidermoids)

Squamous epithelial cyst with adherent keratin debris, consistent with dermoid cyst. H & E, magnification x40.

**CLINICAL FINDINGS**

- Local neural deficits, headache, or meningitis.
- Dermoid cyst rupture - previously thought to be uniformly fatal.

**IMAGING**

- CT - hypodense and avascular, no contrast enhancement.
- Extracranial cranial lesions show typical bony erosive changes seen with epidermoids.
- MRI - more signal heterogeneity than epidermoids; high fat content - high signal on both T1- and T2-weighted images - unique tumor
- Nonenhancing (rare cases of capsule contrast enhancement and even enhancing mural nodule should raise suspicion for neoplastic);
- More solid (than epidermoid tumors) - less likely to grow between neurovascular structures and tend to demonstrate more of local mass effect.
- Edema is lacking.
- Dermoid cyst rupture → fat droplets may be seen throughout subarachnoid or intraventricular space, localized dissemination in sulci causing widening, perhaps contained by pia or inflammatory tissue; hydrocephalus secondary to CSF obstruction by fat droplets.

**TREATMENT**

- Surgical extirpation is treatment of choice - less problematic (than epidermoid tumors) because of firmer consistency, adherence of tumor capsule to vascular and neural structures → more conservative surgical approach.
- Complete excision decreases risk for both postoperative chemical meningitis and tumor recurrence.
- Tumor recurrence has been reported → reexcision.
- No current role for radiotherapy or chemotherapy.

**COLLOID CYSTS**

- Gliotic benign tumors that can cause sudden death because of their location (almost always found in 3rd ventricle → obstructive hydrocephalus).
- 0.5-1% of all primary brain tumors (15-20% of all intraventricular masses).

**ETIOLOGY**

- Possible sources:
  a) In 1930, Spjut hypothesized that colloid cysts are remnants of paraphysis (embryonic midline structure within diencephalic roof immediately rostral to telencephalic border, in posterior lip of foramen of Monro) - cells of paraphysis are similar to those found in colloid cysts (i.e. low columnar epithelial cells without cilia or blepharoplasts) - colloid cysts were called paraphysial cysts for 50 years.
  b) Diencephalic ependyma
  c) Invagination of neuroepithelium of ventricle
  d) Respiratory epithelium of endodermal origin.

**PATHOLOGY**

- Gliotic in anterior superior portion of 3rd ventricle between fornices, immediately dorsal to Monro foramen
- Also have been reported to arise in septum pellucidum, 4th ventricle, sella turcica.
- Attached to roof of 3rd ventricle (and frequently to choroid plexus).
- Gross appearance of small white ball
- Lined with simple or pseudostratified cuboidal or low columnar ciliated epithelial cells (PAS-positive; stain positively for S100 and negatively for glial fibrillary acidic protein, vimentin, and neurofilament).
- Epithelial lining secretes mucinous fluid (greenish, of variable viscosity and can be rubbery) → cyst enlargement.

**CLINICAL FEATURES**

- Classic: intermittent obstructive hydrocephalus with paroxysmal headache associated with changing head position (large cyst obstructing Monro foramen).
- Positional headache:
  - Usually present in age 20-50 yrs (youngest reported case - 2-month-old infant).
  - Other reported symptoms (sometimes related to changes in posture):
    - Sudden weakness in lower limbs associated with falls without loss of consciousness.
DERMOID, EPIDERMOID, CYSTS, LIPOMA

- symptoms similar to normal pressure hydrocephalus (dementia, gait disturbance, urinary incontinence).
- short memory deficits due to fornix stretching!
- Mental changes are common (may persist after surgery if fornix is damaged)!
- look for papilledema.
- sudden death (incidence appears to be low) has been reported; may not correlate to tumor size, degree of ventricular dilatation, or duration of symptoms; suggested mechanisms:
  a) acute hydrocephalus
  b) hypothalamic dysfunction

DIAGNOSIS
CT - well delineated, round or ovoid, homogenous, 66% hyperdense (to surrounding parenchyma) and 33% isodense.
- 90% are 5-25 mm.
- typically nonenhancing and uncalcified (occasional thin rim of enhancement).
- viscosity* of cyst contents correlates more closely to radiodensity on CT than to density visible on MRI.
  * viscosity determines most appropriate surgical approach; hyperdense cyst is more likely to have solid contents - more difficult to drain, but reduced capacity to enlarge over time.

MRI - hypointense on T1 and hypointense on T2.
- amount of rim enhancement is variable.
- MRI differentiates colloid cyst from basilar tip aneurysm (may have similar appearance on CT).

TREATMENT
Immediate attention to hydrocephalus!

Strategy:
- a) large cyst & hydrocephalus → surgery.
  - if patient is too ill → bilateral CSF diversion or unilateral with septostomy (suboptimal because sudden death has been reported in absence of acute obstructive hydrocephalus)*
- b) small cyst, large ventricles, few or no symptoms → observation with serial MRIs.
- c) small cysts and normal-sized ventricles → observation.

N.B. prevention of sudden death is not indication for surgery in asymptomatic patients with small cysts and no hydrocephalus!
- explain to patient that cyst stretches fornix - look for preoperative short memory deficits – those may worsen postop if fornix is further violated surgically.

TREATMENT - SURGERY

a) endoscopic-transventricular approach – only if hydrocephalus is present
b) transcortical-transventricular approach – only if hydrocephalus is present
c) transcallosal approach – see p. Op340

d) subfrontal lamina terminalis approach

Surgical approaches

Transcortical approach
The transcortical approach involves making corticectomy over middle frontal gyrus and proceeding to frontal horn of lateral ventricle. Intraoperative ultrasonography may aid in approach to ventricle. The Monro foramen is visualized at convergence of septal veins, thalamostriate vein, and choroid plexus. The fornix arches over superior and anterior margins of foramen. Avoiding fornix is important because unilateral fornix damage has been associated with amnesia. The cyst should be readily visualized through foramen. The cyst is punctured and contents are aspirated, internally decompressing walls of cyst.

Avoid excessive retraction of walls of lateral ventricle because genu of internal capsule is in subependyma. Other concerns include damaging thalamostriate veins, which can result in basal ganglia damage. After cyst has been decompressed, completely remove it in order to prevent recurrence. Leaving small portion of cyst behind may be necessary if it is attached to either thalamostriate or internal cerebral veins.

Intraoperative photograph through operating microscope shows colloid cyst in Monro foramen. Choroid plexus is observed overlying cyst, and thalamostriate vein is along inferior border.
Endoscopic approach

The endoscopic approach is same as transcortical approach, with exception that former is accomplished through burr hole. The cyst is punctured and aspirated through working channels of endoscope. The endoscopic approach is least invasive, but it can be used only on cysts that can be aspirated. Hydrocephalus can persist after surgery, even after resection of cyst. This complication may be secondary to spillage of cyst contents or to bleeding during surgery. A ventricular catheter may be placed intraoperatively to safeguard against ventricular dilatation.

Postoperative Follow-up

Hydrocephalus may develop despite cyst removal; H: periodic CT. Cyst may recur if partially excised!

ARACHNOID CYSTS

- arise anywhere on brain surface
- some: grow to remarkable size
- smooth surface (vs. EPIDERMOIDS - cauliflower-like deep clefts)
- no diffusion restriction on DW-MRI (vs. EPIDERMOIDS - diffusion restriction)
- never calcify!
- majority are incidental findings - best left alone; surgical fenestration in symptomatic cases (headaches, dizziness) yields good results.

LIPOMA

- derived from mesoderm.
- occur chiefly in midline (esp. over corpus callosum*, vermis, quadrigeminal cistern, spinal dural sac).
- majority are incidental findings.
- characteristic appearance on both CT and MRI - fat density; calcification is frequent in periphery.

MUCOCELE

Frontal mucocele (contrast MRI): large mucocele compressing frontal lobe, with chronic inflammation of nasal mucosa obstructing nasal sinuses.
