PREOP

Detailed preop imaging studies - large lesions may distort normal anatomy (esp. vessels – consider CT)

angiography is important in evaluation of lesion’s vascular supply and venous drainage (prior to interhemispheric dissection)

preoperative tumor embolization can decrease intraoperative blood loss.
surgery is scheduled on elective, but preferably urgent, basis.

Determine Resectability

In almost every instance in which brain tumor is diagnosed, first consideration is its surgical resectability!

exception - multiple brain metastases

Surgery should be first therapeutic modality for tumor!

even potentially curable tumors (such as meningiomas or acoustic neuromas) may reside in positions that make complete resection technically impossible?

only 46% of malignant gliomas in USA are gross totally resected (mostly for fear of functional deficits; other gliomas – only cytodestructive resection); how it can be improved

iMRI for ependymal mapping (BOLD - shows increased venous drainage [not electrical activity of neurons] from active cortex).
It is rare that craniotomy must not be done because of poor general medical status. anesthesiawith lack of effect on ICP.

MANIPUL (1 g/kg) + hyperventilation (Peaco 25-30 mmHg) for definitive ICP reduction in preparation for brain resection. administration time varies – some experts give only at the beginning of “bone work”, others give at the time of prep start (Dr. Broaddus “It takes 10 minutes for mannitol to start working and those 30 minutes are with increased rheological bleeding; mannitol peak effects lasts about 4 hours”).

dexamethasone (usually 10 mg IV) should be administered before manipulating nervous tissue. AED if cortex will be violated or significant resection of lobes is expected.

some routinely administer neuroprotective IV (during induction of anesthesia) - tumor labeling on fixed tissue postoperatively.

**ANESTHESIA**

- in era of modern neuroanesthesia, it is rare that craniotomy must not be done because of poor general medical status.
- anesthesiawith lack of effect on ICP.
- increasing number of resections in dominant hemisphere are done under local anesthesia for purpose of speech mapping.

**APPROACH SELECTION**

For craniotomy details – see p. Op310 >>

Tumors that reach cortical surface are approached through craniotomy at that site.

Subcortical tumors are approached through:

- deep sulci (vs. gyral crown) avoiding eloquent areas (e.g. approaching lesion obliquely).
- cortical incision is ± 3 cm in length.
- anterior corpus callosum (causes minimal, if any, deficit).
- dilated ventricles (intraventricular neoplasms).
- localization of subcortical tumors:
  - intraoperative ultrasonography
  - frameless MRI-guided navigation (markers on patient's scalp).

**SURGICAL PRINCIPLES**

For craniotomy details – see p. Op310 >>

There is no surgical method that can eliminate all of obstacles.

**POSITION**

- prone position is comfortable for surgeon (registration for navigation might be challenging – solutions: a) skin fiducials, b) D-arm automatic registration.
- sitting position - risk of air embolism, less comfortable for operating physician, but field is much clearer because drainage is easier.
- head is held rigidly with pins fixed to minimize movement (for infants, use soft rings - pins can perforate infant's skull or cause depressed fracture, may use pediatric pins).

**MONITORING**

- intraoperative cranial nerve monitoring alerts surgeon when nerves are at risk of damage; cranial nerves II, III, IV, V, VI can be monitored intraoperatively (e.g. C7N monitored with EMG, C8N monitored with BEARS)
- intraoperative electrocorticography (ECOG) is useful in guiding epilepsy surgery, e.g. tumor-associated epilepsy (esp. in long-standing or severe seizures).
BRAIN RELAXATION

- dura is opened only after brain has been softened completely by mannitol diuresis and intraoperative hyperventilation (sometimes few minutes' wait is necessary - this brief pause can be critical to success!).
- in some cases, it is worth placing lumbar drain to drain CSF - causes further brain relaxation.

OPERATIVE CORRIDOR

1. Sulcal approach to limit cortical manipulation (need to access large lesions deep in brain may make this too confining). No gyrus should be entered, unless it is involved in tumor.
2. Use natural corridors:
   1) fissures (do not violate normal cortex); e.g. medial temporal* - tumor - approach from Sylvian fissure split above Sylvian vessels (up to choroidal fissure).
   - medial temporal region (memory) is phylogenetically different than lateral (Wernicke, auditory); tumors do not spread between these regions.
   2) sulci (e.g. for choroidal retractor - atrumatic transsulcal approach)
   3) ventricles – to operate endoscopically (through ventricles), need large hydrocephalus (e.g. clump EVD at midnight - enlarged ventricles can be used to surgeon's advantage in limiting access).
   - optimal corridor to ventricles should not compromise neurological function through direct manipulation of eloquent cortical structures (shortest pathway to lesion is not necessarily best option).
   - deliver lesion into field of view without excessive retraction (requires patience)
   - one of most common causes of postoperative neurological deficits is excessive retraction (to expose mass or to stop bleeding).
3. Corticotomy (most likely at cortex closest to tumor surface) - coagulate with bipolar + cut with microscissors / spread with bipolar prongs (or sucker tip).
   - incisions through cortex or corpus callosum should be covered with absorbable hemostatic barrier* (such as Surgicel or Gelfoam, cotton swab to keep fluid contained) - *make sure material does not fall into ventricle to cause obstruction.
4. Retractors - Greenberg retractors.
   - for intraventricular tumors use Vycor / BrainPath retractors (connect to Greenberg frame) / Greenberg retractors.
   - handheld retractors are less traumatic retraction (injury).

BLOOD SUPPLY

Early access to blood supply – obtain proximal control.
- initial portions of tumor resection should be directed toward gaining access to vascular supply.
- intraventricular tumors may receive blood supply from choroidal vessels of both anterior and posterior circulations.
- exsanguination is likely cause of earlier reports of high mortality in infants with choroid plexus papillomas.
- preserve vessels (they may be en passage - violating them will cause stroke); if both arterial and venous supplies of structure are to be sacrificed, arterial supply should be interrupted first (to avoid congestion, bleeding, and swelling).

TUMOR RESECTION

1. Piecemeal removal of large masses (bipolar & gentle suction, CUSA): debulking tumor center – dissecting remaining shell from surrounding normal brain tissue by advancing parties / Tefla into interface (i.e. resection proceeds from inside out so that surrounding normal white matter is disturbed minimally).
   - N.B. resist temptation to pull the tumor en bloc – there could be a critical vessel attached to tumor base (where you cannot see and can be avulsed), also tumor base can be attached to dural sinus wall, etc.
   - may use saline spray with blunt needle tip to open plane.
   - piecemeal resections will result in bleeding, and many times this cannot be avoided.
   - intraventricular bleeding → blood from pooling in ventricles should not compromise neurological function through exsanguination (risk of postoperative ventricular obstruction and probably postoperative headache).
   - “*if foramen of Monro cannot be cleared of obstruction, open window in septum pellucidum (almost routinely).”
   - early reports of lateral ventricular tumors that display entire lesion as gross pathological specimen clearly demonstrate why surgery caused profound neurological deficits and high mortality.
   - removal of firm, adherent, or calcified tumor is simplified by Cassitron ultrasonic aspirator (CSUSA) - tip vibrates at 22,000 Hz - ultrasonically disrupts tumor; tip is surrounded by two concentric channels, one dispensing saline to solubilize fragments and another suctioning away (*cotton square to protect Munro with cotton square) - to avoid obscuration of this structure and to prevent blood from pooling in ventricles) - *coupons irrigation (risk of postoperative ventricular obstruction and probably postoperative headache).
   - for low grade glioma – remove entire gyrus using bipolar dissection - hold edge of pia with pickup and suck parenchyma with sucker along pial inner surface.
2. Total resection should be goal of surgery.
   - glinting peritumoral white matter is seen easily through microscope as tumor's margin is reached at this interface resection is stopped.
   - incomplete removal may be preferable when site of attachment invades into deep structures such as thalamus (goal is debulking when mass effect is cause of symptoms).
3. Intralesional (piezoelectric) vs. circumferential perilesional (en bloc) resection
   - GBM is known to be infiltrative, and thus a true en bloc resection is not possible
   - intralesional fashion - contrast enhancing portion of the tumor is entered, and the tumor is removed from the center toward the edges.
   - perilesional fashion:
     - intraoperative ultrasonod and stereotactic image guidance identify the cortical margins of the tumor and its subcortical extension.

- see “Awake craniotomy” in p. Op300 –

MAPPING OF ELOQUENT CORTEX

- see “Awake craniotomy” in p. Op300 –
because the tumor is not “decompressed”, shift does not happen and computer-assisted surgical guidance is relatively well maintained throughout the case.

- perilesional tumor resection was associated with a significantly higher rate of GTR than intracranial resection (83% vs 62%, multivariate odds ratio = 2.5).
- among tumors in eloquent cortex, perilesional resection had a higher rate of GTR (79% vs 58%, respectively, P < 0.001) and a lower rate of neurological complications (11% vs 20%, P = 0.018).

<table>
<thead>
<tr>
<th>EXTENT OF TUMOR RESECTION</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Goal</strong> - resection of maximal amount of tumor consistent with functional preservation</td>
</tr>
<tr>
<td>gross total resection may extend survival from around 11 to 14 months in glioblastoma and from 60 to 90 months in low grade glioma (Sanai 2009).</td>
</tr>
</tbody>
</table>

High-grade gliomas – see p. Onc10 >>
Low-grade gliomas – see p. Onc10 >>

**TUMOR FENCING** - inserting along tumor perimeter (using navigation, before tumor resection – to avoid shift) Becker ventricular catheters (cut flush to brain surface but still tend to fall out – so suture to dura edges) or strings of patties. During tumor resection keep going until encounter “fence poles” – serve also as depth guides (not just perimeter guides).

**VENTRICULAR ENTRY** - during resection of high-grade gliomas (HGG):
- Cancer Dissemination, Hydrocephalus, and Survival After Cerebral Ventricular Entry During High-Grade Glioma Surgery: A Meta-Analysis Alabianthamer M Moore, MD Patrick D Kelly, MD Reid C Thompson, MD Lola B Chalmers, MD Neurosurgery, ny202, https://doi.org/10.1093/neuros/nyy202 Published: 22 May 2018
- higher odds of leptomeningeal dissemination ($OR$: 3.91 [95% confidence interval (CI): 1.89 - 8.10]; P = .0002; 86/410 vs 57/847 patients in 9 studies
- higher odds of hydrocephalus ($OR$: 7.78 [95% CI: 3.77 - 16.05]; P < .0001; 58/431 vs 11/565 patients in 11 studies)
- decreased survival (median survival: 16.8 vs 19.1 mo; 413 vs 322 patients in 10 studies; hazard ratio: 1.25 [95% CI: 1.05 - 1.48], P = .01).
Intraoperative MRI (iMRI, ioMRI)

- be aware of thin rim enhancement along the surface of the resection cavity artifact caused by surgeon’s mechanical disruption to BBB - may be difficult to distinguish from tumor-specific enhancement (esp. when a low-resolution 0.15 T magnet is used).

FLUORESCENCE-GUIDED RESECTION (S. CHEMONAVIGATION)

- 5-ALA and iMRI work synergistically!
- fluorescence gives 2-D real-time surface information and may sometimes be hidden behind overhanging edges or obscured by blood, can be used to wisely augment the capabilities of more complex and non-real-time iMRI, which gives 3-D information, to safely optimize resections.

INTRAOPERATIVE FLUORESCENCE IMAGING

- 20 mg/kg IV at dural opening - 560 nm microscope filter
- contraindication – serum creatinine > 2 mg/dL
- labeling mechanism is based on BBB leakage (during surgery BBB gets damaged anyways – false positive labeling).

FDA APPROVAL

- FDA approval (first drug approved in US based only on European trials)
  - June 6, 2017 - FDA has approved Gleevec® (imatinib mesylate) as a small molecule kinase inhibitor.
  - June 13, 2017 - FDA has approved Gleolan® (5-aminolevulinic acid hydrochloride (ALA HCl)) as an optical imaging agent indicated in patients with gliomas (suspected World Health Organization Grades III or IV on preoperative imaging) as an adjunct for the visualization of malignant tissue during surgery.
  - commercially in US became available in October 2018.

Mechanism of action:

- 5-ALA is metabolized to protoporphyrin IX, an endogenous fluorescent bisabolol, as part of the heme biosynthesis pathway.
- in malignant glioma cells, but not in healthy brain cells, exposure to 5-ALA results in tumor-specific accumulation of protoporphyrin IX as a result of alterations in enzymes and cell transporters involved in heme biosynthesis - useful for the intraoperative discrimination of tumor and normal tissue in the operating room, as well as 5-ALA – based photodynamic therapy.

Practical:

- Indication: high-grade gliomas (suspected WHO grades III-IV on preoperative imaging).
- contraindication: porphyrins.
- 20 mg/kg (1 vial, 2700$ = 1 vial) is taken PO 3 hours (range 2 to 4 hours) prior to induction of anesthesia.
- N.B. there is no data on redosing!
- Must be reconstituted 1500 mg/50 mL of water per vial
- 5-ALA leads to accumulation of fluorescent porphyrins (protoporphyrin IX) in tumor tissue.
- max fluorescence time is 5-8 hours.
- false positive – metastases, inflammation.
- positive predictive value – 95%.
- false negative:
  - necrotic tissue will not fluoresce.
  - intensity of fluorescence will diminish as a function of the focal distance of the microscope beyond 300 µm from the tumor, which is the point at which it becomes increasingly difficult to adequately visualize tumor fluorescence - fluorescent energy declines by the 4th power of the focal distance.
  - fluorescence intensity will diminish with time of light excitation due to photobleaching upon exposure to light.
- target region is exposed to blue laser light with 405 (375-440) nm peak wavelength (with handheld device or microscope):
  - there is a phantom available to test microscope (blue light source must be used) alongside a laser light for adequate visualization of fluorescent porphyrins in tissue.
  - surrounding infiltrated tissue glows orange.
  - tumor tissue glows red (620-710 nm), operative video >>
- reduce exposure to sunlight or room lights for 48 hours postoperatively (place wristband on the patient indicating the time when this 48-hour period will end).
- do not administer photosensitizing agent for 24 hours per and 24 hours postoperatively - phototoxic skin reaction (severe sunburn) may result: St. John’s wort, griseofulvin, thiazide diuretics, sulfonylureas, phenothiazines, sulphonamides, quinolones, and tetracyclines.

Pharmacokinetics (PK), Pharmacodynamics (PD):

- drink room temperature.
- vial wrapped in yellow bag.
- mean absolute bioavailability - 100%.
- maximum ALA plasma concentration - within a median of 0.8 hour.

BRAIN TUMOR SURGERY Op.340 (5)
When bulk of tumor has been removed, further search for additional tumor is carried out and such are preserved. Hemostasis during dissection is of utmost importance. Care must be taken against undermining or even excessive retraction of functional cortex to be outside the tumor. When this is impossible, aspiration must begin within tumor.

Resection of infiltrating lesions requires debulking of mass and seeking plane between tumor and edematous brain. Some tumors present with false capsule, but such lines of demarcation are often difficult to isolate. If ventricle is sometimes difficult to drain and, when possible, fenestrated into adjacent ventricle to prevent reaccumulation of tumor cysts. Volume of fluorescing tissue is about double the volume of enhancing regions — new MRI contrast enhancement in glioblastoma surgery. J Neurooncol. 2012;108(2):181–203.

Fluorescence extends even beyond the fluoro-ethyl-tirosine-PET zone of hypermetabolism.

CLOSURE

- tumor cavity is then examined for bleeding points, and meticulous hemostasis is achieved prior to closure.
- persistent bleeding may be due to residual tumor, and it will require direct bipolar cauterization or topical gelatin foam, which is secured prior to closure.

Allen

The pia-arachnoid is opened using bipolar coagulation along line of incision which is made by sharp dissection. It is usually safe to make subtotal dissection to adjacent sulci, continuing into white matter and leaving plane between tumor and edematous brain. Some tumors present with false capsule, but such lines of demarcation are usually delimited. Generally, brain substance is divided by suction or blunt dissection. Division of low-grade gliomas or sclerotic areas may require sharp dissection or ultrasonic aspiration. Dissection around base of tumor continues until tumor is isolated. If ventricle is opened, it should be walled off to prevent blood from collecting within it. If cortex is reached opposite entry site, cortical vessels must be individually occluded and divided by sharp dissection. The plane of dissection can be preserved by use of cottonoid strips to protect brain. Planes of dissection can usually be developed between metastatic lesions and surrounding brain, aided by strips of cottonoid to wall off brain. Bridging vessels are divided, and separation along lines of cleavage is continued until tumor is surround.

Many infiltrating lesions have pseudocapsules that may be well-demarcated, but currently such lines of demarcation fade out so that tumor can no longer be separated from surrounding normal brain. In other cases where infiltrating lesion is limited to lobe, standard lobectomy may be selected, dividing pia and pial vessels, and transecting lobar structures so as to include neoplasm. If cortex is reached opposite entry site, cortical vessels must be individually occluded and divided by sharp dissection. Ultrasonic aspiration may supplement suction and coagulation. Resection of infiltrating lesions requires debubbling of mass — usually by aspiration and often with ultrasonic aspiration. Generally, blood loss from highly vascular neoplasms will be less by working at edge of tumor. When this is impossible, aspiration must begin within tumor. Care must be taken against undermining or even excessive retraction of functional cortex to be preserved. Hemostasis during dissection aids visualization of structures and identification of vessels. When bulk of tumor has been removed, further search for additional tumor is carried out and such fragments are removed. The ultrasonic aspirator is helpful in this maneuver.
extubation:

a) if surgery entails significant manipulation of brain stem, patient should remain intubated for first postoperative night and be extubated carefully once lower cranial nerve function has been assessed;

b) if brain stem involvement was minimal, patient may be extubated in operating room.

SIDE EFFECTS

- ICU for at least 1 night, increasing trend for selective ICU admission (“ICU, unless” — “no ICU, unless”) — reduced complication rates and length of stay while keeping patients satisfied s hospital costs related to the admission have been significantly reduced.

- Serum electrolyte levels and homoestasis are measured often (also to detect possible onset of SIADH or diabetes insipidus, esp. after endocavitary manipulations).

STEROIDS

- Continue steroid therapy for at least 5 days (to minimize surgically induced brain edema);

- If adequate surgical decompression is achieved, steroid can be discontinued within first 1-2 weeks;

- Speed of weaning depends on:
  1) postop new deficits
  2) amount of edema on postop FLAIR MRI

- Indications for steroid maintenance:
  1) Large volume of tumor remnants, large edema ∆ check on postop MRI
  2) Unexpected (likely from edema) new / worsening postoperative deficits
  3) Tumor in brainstem or spinal cord
  4) Steroid dependence

- Corticosteroids again may be needed during or after radiation therapy.

AEDs

- Continue anticonvulsants for at least 7 days (few recommend 1 year);

- Incidence of seizures after surgery for brain tumors is low (8% [95% CI 3%-18%]) even without prophylactic AEDs, and incidence of clinically significant seizures is even lower (3%).

- Even for patients with preoperative seizures, postoperatively for most seizures cease spontaneously (when patients are initially seizure free after surgery, seizure recurrence is associated with tumor progression).

- If mechanism by which a seizure may occur in setting of neurosurgery for tumors:
  1) intrinsic epileptogenic nature of the tumor, particularly in certain locations such as temporal and parietal lobes
  2) surgical factors associated with craniotomy (brain retraction and cortical irritation)
  3) Postoperative complications (hydrocephalus, edema, or infection).

- Traditional AEDs are potent enzyme-inducing (Phenytoin, Carbamazepine, Phenytoinibital) or inhibiting (valporate) — reduce / increase serum concentration of chemotherapeutics.

- New generation of AEDs (Gabapentin, Levetiracetam) are not metabolized by CYP isoenzymes.

There are studies that do not support prophylactic AED use:

- Patients undergoing resection for brain tumors without a previous history of seizures (Phenytoin vs. placebo for 7 days postop).

- Incidence of all seizures was 18% in observation group and 24% in prophylaxis group (p = 0.51).

- Incidence of early seizures (< 30 days after surgery) was 8% in observation group vs. 10% in prophylaxis group (p = 1.0).

- Incidence of clinically significant early seizures was 3% in observation group and 2% in prophylaxis group (p = 0.62).

- Prophylaxis group experienced significantly more adverse events (18% vs. 0%, p < 0.01).

- Review of 698 patients

- No significant differences in incidence of early or late seizures between AED and no-AED cohorts.

- Conclusions - prophylactic administration of anticonvulsants during resection of supratentorial meningiomas provides no / significant prevention of both early or late postoperative seizures.

ANTEMPOREOL MEASURES

- Compression boots, subQ heparin immediately postop → early passive exercises and mobilization!!!

POSTOPERATIVE IMAGING

- Baseline contrast MRI within 48 hours - to evaluate resection success (later, prominent enhancement of neovascularized reactive gliosis - interferes with image interpretation); absence of abnormal enhancement indicates gross total resection.

- Look at DWI and ADC - postcontrast MRI may show great tumor resection but if there is adjacent stroke it will start enhancing (as natural evolution) 3-4 weeks later and radiologist will call it "tumor progression".

- For tumors with propensity for leptomeningeal spread (Medulloblastoma, Ependymoma, Craniopharyngioma, Certain pineal germinomas), test before further postoperative therapy:
  1) CSF cytologic examination at least 2 weeks after surgery (LP is safe ≤ 10-21 days after intracranial decompression);

- Some authors suggest obtaining CSF at time of surgery from cisterna magna for cytologic analysis.

- Spinal MRI yearly during first 24 months (CSF exam alone is inadequate — may be false negative in up to 30% cases), routine spinal evaluations beyond this time may not be practical / local recurrences are far more likely.

- If MRI is contraindicated, CT myelography is utilized.

- N.B. Baseline spinal MRI is best done prior to surgery (to avoid postoperative artifacts); first postoperative spinal MRI - at least 2 weeks after surgery (spinal canal enhancement can occur in early postoperative period); if equivocal - repeat after 1-2 weeks (artifacts secondary to surgery regress while drop metastasis remain stable or increase).

ROUTINE SURVEILLANCE (unwarranted in asymptomatic patients following complete resection of benign tumors)

- Every 3-6 months during first 2 years;

- Every 6-12 months for following 2-3 years;

- Every 3-5 years (for detection of late events such as radiation-induced meningiomas).

- Residual or recurrent contrast enhancement ≤ 3 months after surgery suggests recurrence.

- N.B. true tumor progression cannot be confirmed on MRI prior to 3 months!

- Differentiation of residual tumor from scar (region of linear, rim enhancement) is improved by gadolinium.

https://doi.org/10.1093/neuros/nyz388 Published: 20 September 2019

COMPLICATIONS

- **operative MORTALITY** rates are < 1%; 30-day mortality rate after brain tumor surgery is 2.2-2.9% - postoperative hematoma is the most frequent cause of death. 
  - incidence of a POH requiring a recraniotomy was 2.09%.
  - among recraniotomy patients, 12.5% died within 30 days of the first surgery.
  - a postoperative hematoma is the most frequent cause of death.

- **operative MORBIDITY** depends largely on tumor location (highest – 10-20% – in diencephalic tumors).
  - incidence of a hemangioblastoma, infratentorial tumors, and a prolonged operative time (>10 h).

SKULL BASE TUMORS

ANTERIOR SKULL BASE

See also p. Op300 >>

CAVERNOUS SINUS AND MIDDLE FOSSA

PINEAL REGION TUMORS

POSTERIOR FOSSA TUMORS

- EVD can be placed frontally prior to positioning or occipitally once the patient has been positioned
- place EVD in OR prior to craniotomy (or at least prep for occipital Frazer bur hole)
- important to avoid hypertension immediately postop – risk of bleeding into posterior fossa!

CEREBELLOPONTINE ANGLE, 4TH VENTRICLE

Vestibular schwannoma – p. Onc62 >>

BRAINSTEM TUMORS

CEREBellar Tumors are best approached along the shortest transparenchymal route to the lesion
A. Superior hemispheric lesions - via the supracerebellar cistern and by incising the cerebellum at the closest point to the tumor - requires a high suboccipital craniotomy with exposure of the transverse sinus.

B. Inferior cerebellar tumors require opening of the foramen magnum.

C. Midline tumors can be resected after splitting the inferior vermis.

D. Lateral hemispheric lesions - directly from a posterior trajectory; entering the paracerebellar cisterns is generally not necessary, thus avoiding exposure of the cranial nerves; split hemispheric pia horizontally (parallel to widened folia):

- postoperative deficits:
  1. Cranial nerve deficits
  2. CEREBELLAR MUTISM (anatomic origin - deep cerebellar nuclei) - one of most commonly cited complications.

HEMANGIOBLASTOMA

A. Cerebellar lesions - via suboccipital craniectomy; Hydrocephalus → external ventricular drain prior to tumor resection! (hydrocephalus resolves in > 90% patients postop)

B. Spinal lesions - via laminectomy:
  1. no syrinx → remove upper ones (tumors); syrinx present → remove largest one (tumor) – syrinx resolves in 1-3 months (if not – means residual tumor)
  2. target - mural nodule (otherwise, cyst will recur); no need to resect capsule if it is nonenhancing on MRI
  3. surgical principles similar to those used in treating AVMs:
     - pre-operative embolization may help reduce the vascularity.
     - identify feeding vessels → coagulate and cut (arterial feeders prior to draining veins?)
     - do not remove in piecemeal fashion - significant bleeding may ensue!
- coagulate tumor surface (to shrink the tumor) with wide bipolar forceps (avoid penetration of tumor itself due to its extreme vascularity and difficulties with hemostasis).
- dissect tumor circumferentially by careful devascularizing blood supply (coagulation and cutting small feeding vessels), releasing adhesions between tumor and surrounding tissue by putting cottonoid strips into developing plane to avoid direct pressure on brain or spinal cord tissue. — HGBs with attachment to floor of 4th ventricle may be hazardous to remove (cardio-respiratory complications).
- gently pack resection cavity with wet cotton balls → blood oozing stops after few minutes.
- need for permanent shunt is determined by response to EVD clamping.

N.B. all patients must be screened for PHEOCHROMOCYTOMAS preop (may cause perioperative hypertensive crisis induced by anesthetic or analgesic agents) - 24-hour urine free cortisol or plasma concentrations of metanephrine and normetanephrine → CT; if evaluation reveals pheochromocytoma → resect pheo first (if resection is prohibitive, preoperative α-blockade with β-blockade begun only after α-blockade to avoid unopposed α-activity)

THIRD VENTRICLE

Pending read:
Approaches to the Third Ventricle - Interhemispheric Transcallosal

A. Transcortical approach – facilitated by ventriculomegaly
B. Transcallosal (interhemispheric) approach – equally effective in reaching foramen of Monro with large or small ventricles

A. Transforaminal approach
B. Transchoroidal approach
C. Interforniceal approach
• experts say that it is OK to divide massa intermedia.

**Endoscopic Transventricular Resection of 3rd Ventricle Colloid Cyst**

Pending

Jandial, procedure 47

**Transforaminal Resection of 3rd Ventricle Colloid Cyst**

• lesions in the anterior portion of the third ventricle are often easily accessible through the foramen of Monro and sometimes even expanded and protrude through the foramen.

- for lesions that are soft or cystic, it is often appropriate to resect and deliver the lesion through the foramen of Monro.

- lesions with significant mass effect sometimes already have caused dilation of the foramen, facilitating the surgical approach; foraminial patency can be assessed with the use of forceps or with probing with a Silastic shunt tube.

  N.B. dilating the foramen can lead to postoperative memory deficits due to fornix injury! Also lateral side of foramen of Monro is made of genu of internal capsule!

- dexamethasone, mannitol, no AED.

- frontal parasagittal craniotomy:
  - supine position with head in Mayfield headholder
  - lazy-S incision with head in Mayfield headholder, just in front of coronal suture (two thirds anterior and one third posterior to coronal suture; there are no bridging veins near coronal suture)
  - 2 bur holes (4 cm apart) with Acorn drill bit over superior sagittal sinus; time should be taken to dissect the dura carefully from the inner table working away from the sagittal sinus, correct bur holes with footplate – one side just parasagittal, other side 3 cm from midline
  - dura reflected towards sagittal sinus
  - Greenberg/Budde retractor, microscope
  - gentle retraction of frontal lobe away from falx.
  - separate both cingulate gyri
  - bilateral pericallosal arteries gently separated
  - 1-2 cm midline callosotomy using microsuction tip (verify with navigation trajectory)

  N.B. corpus callosum is very shiny, brightly white!

- enter lateral ventricle.

- venous angle and choroid plexus lead into foramen of Monro.

- incision into tumor capsule and attempt debulking with pituitary retractor (may fail due to rubbery nature of cyst contents).

- very gentle tumor rocking allows tumor delivery into lateral ventricle via foramen of Monro.

Postoperative – see p. Onc30

**Transchoroidal Approach**

- entering either above or below the choroid plexus in the body of the lateral ventricle

- access into the third ventricle through the velum interpositum, which serves as the roof for the third ventricle.

- supracallosal approach - incision is made in the taenia chooroidea, and the choroid plexus is reflected upward; may be necessary to cauterize one of the thalamostriate veins, which may be a limiting factor in the untethering of the choroid – potential consequences of sacrificing a unilateral striate vein include hemiplegia, mutism, and drowsiness.

  *these postoperative morbidities may not occur; however, because of collateralization by superficial cortical, posterior medullary, and galenic venous systems

  supracallosal approach (correct route on board exam for transchoroidal approach) - incision is made above and medial to the choroid plexus in the taenia fomica, and the choroid is deflected inferiorly - approach requires less manipulation of the superficial thalamic and caudate veins - safer.

**Interforaminal Approach**

- midline division of the fomical bodies

- bilateral fomical injury can occur through manipulation – devastating memory impairment - approach is reserved for cases in which there is significant mass effect that distends the roof of the third ventricle.

- during development of a dissection plane in the interforaminal approach, remain cognizant of the hippocampal commissure in the posterior component of fornices.

- preserve and retract gently the internal cerebral veins (appearance may mimic colloid cyst)
**LATERAL VENTRICULAR MASSES**

Relatively high risk for mortality and neurological morbidity.

Masses in this location:
- often are benign tumors - grow at slow rate - reach very large size before identified.
- cause hydrocephalus (headache, poor balance, difficulty with memory)
- localizing findings (aphasia, agnosia, hemiparesis, etc) are rarely present – mostly occur with entrapment of occipital and temporal horns.

**PREOPERATIVE**
- routine EVD

**OPERATIVE TECHNIQUE**

Also see above for principles >>

**Surgical approaches:**
- Incisions provide access to temporal horn (least likely site for mass lesion).
temporal approaches provide early access to anterior choroidal artery but poor visualization of posterior choroidal vessels (until lesion is almost completely resected).

- if mastoid air cells are entered → close with generous use of bone wax.
- normally temporal horn is approximately 3.5 cm from temporal tip.

Safest temporal corticotomy is ANTERIOR INTERIOR TEMPORAL CYRUS (middle temporal gyrus might be OK on nondominant side)

Access to temporal horn

A. Temporoparietal junction:

1) traverse angular gyrus → dyslexia, agrafia, acalculia, idiomotor apraxia in dominant hemisphere (in nondominant hemisphere - impaired visual memory, construction deficits, neglect).
2) cross optic tracts → visual field deficit

B. Middle-temporal gyrus → high-risk of damage to speech cortex in dominant hemisphere (H: cortical stimulation); in nondominant hemisphere it is acceptable route!

C. Trans temporal horn occipitotemporal gyrus (originally developed for resection of hippocampus in treatment of intractable seizures) - provides exposure to temporal horn and atrium

- may result in superior quadrant field deficit.

PIERIAL LOBE

- incisions contraindicated in dominant hemisphere (→ speech deficits).
- vascular supply is away from surgeon's line of vision.

Access to occipital lobes:

A. Trans temporal horn occipitotemporal gyrus – see above

B. Occipital lobe incision / lobectomy – see below

C. Transcallosal approach – see below

D. Superior parietal lobule incision (first choice approach per Dr. Graham) - most commonly used approach; avoid significant retraction ↔ risk of acalculia and apraxia (dominant hemisphere), visual-spatial processing problems, homonymous hemianopsia and hemiparesis.

- incision should be sufficiently large to permit use of 2-cm retractor blade without tension.
- incision in occipital horn and atrium

- may result in superior quadrant field deficit.

OCCIPITAL LOBE

Occipital lobectomy can provide access to entire ipsilateral ventricle.

- causes permanent loss of homonymous visual field (may be acceptable, if present preoperatively).
- does not permit early access to choroidal vessels – prepare for considerable blood loss.

FRONTAL LOBE

Access to anterior ventricle

A. Transcallosal approach – see below

B. Middle frontal gyrus incisions:

- particularly helpful for tumors with broad ependymal attachment in frontal horn.
- incision in middle frontal gyrus at level of coronal suture (3.5 cm from midline, 1 cm anterior to coronal suture) → direct approach to frontal horn and foramen of Monro.
- significant speech problems may occur even when Broca's area is undisturbed.
- incisions in either hemisphere can result in attention deficits.

CORPUS CALLOSUM (TRANSICALLOSAL INTERHEMISHERCIC APPROACH)

Used literature: R. Jandial “Core Techniques in Operative Neurosurgery” (2011), procedure 8

Pending: Lab Demo - Transcallosal Approach to Lateral & Third Ventricle >>

INDICATIONS

1. Third ventricular tumors
2. Lateral ventricular tumors - relatively safe access to all areas except temporal horn and posterior occipital horn H: transcortical approach.

PROCEDURE

- Brain relaxation is particularly important

- gravity can be used to patient's advantage - patient in lateral decubitus position with involved hemisphere dependent - falls act as retractor to hold contralateral hemisphere while involved hemisphere is gently retracted – greater risk of midline disorientation; other experts (Dr. Graham) prefer straight supine position (neck flexed 45 degrees) – easiest for orientation but it is difficult to work with both hands (instruments above each other).
- long and narrow craniotomy (to parallel interhemispheric corridor).
- arachnoid adhesions can be dense near ACAs – risk of pericallosal artery damage!
- slight change in angle can result in opening wrong lateral ventricle (H: identify septum, pulmoniculum and redirect surgical angle).
- superior portion of mass should be delivered into surgeon's line of view rather than retracting hemisphere to expose it.
- most difficult area to see – inferior lateral corner (roof of basal ganglia, thalamus).
• use **microscope** and Greenberg/Buddle with 3/8 retractor blades.
• access to corpus callosum requires preservation of **medial (bridging) draining veins** (but still provide space for 3-cm retractor blade) - look at preop imaging (MRV/CTV up to formal catheter angiography) for large vessels that may preclude entry.
  - “Dr. Graham’s area” – from 3-5 cm anterior to coronal suture to just (max 2 cm) behind it
  - paucity of bridging veins – best area for craniotomy.
  - most often there are 2-3 large veins that serve medial hemisphere, but there is no clear rule on which may be sacrificed (smallest anterior vein usually can be coagulated and transected if necessary).
  - dissect veins from their pial attachment to reduce tension.
  - near coronal suture there are no bridging veins!
  - open along nondominant (usually right) side
• use **navigation** to limit extent of callosotomy just over tumor
• dissect and retract ACA (pericallosal arteries – place cotton balls to keep those arteries retracted from each other).
• corpus callosum can be identified easily because of its very bright glistening and relatively hypovascular aspect
  N.B. with ventricular masses, there may be midline distortion of corpus callosum (review preoperative imaging).
• callosotomy is done with suction tip; limit AP extent (usually 1-2 cm is enough) – rather go side-to-side (opening corridor by taking already sectioned fibers)
• retractor is gradually (to let ventricles accommodate*) advanced to expose the lateral ventricular anatomy.
  *to prevent venous infarction secondary to overretraction, limit retraction to < 2 cm along any part of the corridor, pauses of 2 to 3 minutes should be observed after every advancement of the retractor blade down the interhemispheric fissure (pause allows for the ventricular pressures to equilibrate in the face of forces exerted by the retractor itself).
• if the foramen of Monro is open, a physical barrier should immediately be placed at its entry to prevent blood from pooling into the third ventricle.
• if contralateral ventricle is entered, fenestration or excision of the septum pellucidum can open access into the ipsilateral lateral ventricle; fenestration of the septum also allows for the alternative pathway for CSF flow.
• fornices travel across the base of the septum and must be preserved.
• following the thalamostriate vein, septal vein, fornices, or choroid plexus reliably guides the surgeon to the foramen of Monro.
• ependymal surface adjacent to the callosotomy and abraded medial and paramedial cortical surface are particularly susceptible to postoperative hemorrhage.
• EVD should be left in the lateral ventricle for about 48 hours postoperatively.
• if expect that redo will be needed in the future, leave gel film in the interhemispheric fissure to prevent adhesions.

Transcallosal exposure of lateral ventricle – choroid plexus entering foramen of Monro
COMPLICATIONS

- disconnection of hemispheres, esp. in patients with anomalous cortical organization (e.g., Wada test prior to transcallosal surgery):
  - mutism, akinnesia, apathy, unilateral weakness (leg > arm), forced grasping, fixed gaze, disinhibition, incontinence, right-left confusion.
  - sectioning of splenium in patients with dominant hemisphere homonymous hemianopia will cause alexia and visual agnosia.
  - transcallosal surgery in left-handed, left-hemisphere speech-dominant and right-handed and right-hemisphere speech-dominant patients can cause agraphia and speech impairment.
  - transcallosal surgery in left-hemisphere speech-dominant patients with right-hemisphere memory only or right-hemisphere speech dominant patients with left-hemisphere memory only could result in memory disorder.
  - certain early childhood injuries can cause reorganization of cerebral function such that interhemispheric communication becomes critical (both hemispheres contribute to speech or unilateral motor function); callosal disconnection → altered speech and motor function.

Crossed dominance, wherein the hemisphere controlling the dominant hand is contralateral to the hemisphere controlling speech and language, is a contraindication. Crossed dominance can arise after cerebral injury during childhood that resulted in cortical functional reorganization. These patients may develop writing and speech deficits postoperatively. Special consideration should be given to cases in which a more posterior callosotomy (splenium) is required, increasing the risks of cognitive dysfunction (e.g., alexia), particularly in patients with established preoperative visual field cuts (e.g., homonymous hemianopsia).

Limited incision of the callosal trunk usually leads to minimal physiologic complications. An acute syndrome of decreased speech spontaneity, ranging from mild slowness of speech initiation to frank mutism, with onset in the hours and days after surgery and possibly persisting for several months, has been described after transcallosal injury. Although longer callosal incisions (2 to 3 cm compared with 0.8 to 2 cm) may be associated with this syndrome, other manifestations of this acute syndrome, including lower extremity paresis, incontinence, emotional disturbance, and seizures, suggest that additional neural structures are likely involved. Mutism may also be caused either by direct retraction of the anterior cingulate gyrus, septum pellucidum, and fornix or by circulatory disturbances of the supplementary motor area, thalamus, and basal ganglia.

Disorders of interhemispheric transfer of information, which can include visuospatial and tactile information and bimanual motor learning, are another potential complication. Although the exact deficits depend on the topographic relationship within the corpus callosum, several studies have suggested that interhemispheric transfer should be preserved as long as the splenium is intact.

- leg motor cortex injury - venous infarction or retraction injury.
- short term memory deficits – from fornix manipulation

COMBINED APPROACHES (TRANSCALLOSAL + TRANSCORTICAL)

a) for masses that are too large to remove through single approach:
- when hemisphere is distended by tumor (rather than by CSF) → transcortical incision and partial decompression to obtain sufficient relaxation → interhemispheric dissection for callosotomy.
- portions of tumor with broad ependymal attachment along superior portion of frontal horn may not be accessible from interhemispheric approach.

b) combined cortical incision and callosotomy can be performed safely in adults.
- transcortical incision usually goes first → safer interhemispheric dissection with relaxed hemisphere.

Case illustration:
POSTOPERATIVE DEFICITS

- visual field loss is one of most common focal deficits.
- hemiparesis is frequently observed during immediate postoperative period.
- speech deficits complicate surgery in dominant hemisphere.
- seizures can occur in any patient (20-70% after transcranial resections; significantly lower after transcortical surgery).
- memory deficits if damaged fornices (e.g. colloid cyst resection).
- subdural hematoma and hygroma are significant problems in patients with preoperative hydrocephalus.
  - avoid excessive CSF drainage via EVD
  - mobilization out of bed should proceed slowly
- postoperative ventricular enlargement is noted frequently in spite of total tumor resection: 35% patients require shunt.
- enlarged ventricles and normal ICP may present condition analogous to NPH.
- incomplete resection occurs in 33-50% cases.
- mortality for surgery on lateral ventricular mass lesion ranges 12-75% (massive brain swelling or intraventricular hemorrhage were most common causes).
  - in one series of meningiomas, all deaths occurred when tumor was removed en bloc.

INSULAR TUMORS

- Berger-Sanai insular glioma classification system - tumor types that may benefit from more aggressive surgery.

MENINGIOMAS

Although meningiomas are benign and potentially curable, total removal may be impossible* without unacceptable destruction of normal structures because of location, compression of vital structures, and vascularity

PREOPERATIVE

- preoperative endovascular embolization of vascular feeders from external circulation is beneficial in extremely vascular meningiomas — resection 0-96 hrs after embolization (to decrease likelihood of tumor revascularization).
  - embolization facilitates surgery by reducing blood loss (esp. when blood supply is on other side of tumor vis-à-vis surgeon’s line of sight)
  - embolization may help to achieve gross-total resection of both skull base and large supratentorial meningiomas
  - embolization is performed using polyvinyl alcohol microspheres (PVA) 150-300 μm; smaller particles (Gelfoam powder) or liquid agents (Onyx, phenytoin, Lipiodol) may provide deeper tumor penetration but increased risk of side effects; other agents: porous cellulose beads, hydroxyapatite, trisacryl gelatin (TAG) microspheres.
  - increasing interest in intraoperative direct needle puncture intratumoral embolization
  - corticosteroids (preoperatively and postoperatively) significantly decrease mortality & morbidity.
  - antiepileptics are started preoperatively in supratentorial surgery and continued postoperatively for no less than 3 months.

PRINCIPLES IN MENINGIOMA RESECTION

- tumor removing technique – using bipolar / Penfield #1, disconnect tumor at base from dura (disconnects blood supply).
  - always start by coagulating arterial feeders to meningioma.
  - if preop MRI shows no or little adjacent brain edema — expect no or minimal leptomeningeal feeders (easy development of tumor-brain plane).
  - involved dura as well as dural rim free from tumor should be resected (→ duraplasty*); dural tails (apparent on MRI) are best removed.
  - *from best to worst results: pericranium > fascia lata > commercial dural substitutes.
    - if meningioma cannot be removed completely — try (if safe) detaching tumor from its dural origin and therefore from its predominant blood supply; then may also cauterize dural surface.

SIMPSON GRADES

- 1: Tumor is completely removed
- 2A: Tumor is incompletely removed, all areas of dura are involved
- 2B: Tumor is incompletely removed, areas of dura are not involved
- 3: Tumor is incompletely removed, some areas of dura are involved
- 4: Tumor is incompletely removed, large areas of dura are involved

INCURSION: TUMOR REMOVAL
### MENINGIOMA INVOLVING BONE

- all involved / hyperostotic bone should be removed.
  - some centers use 5-ALA to guide bone resection (or avoid extensive resections if bone is nonfluorescent and thus likely just with reactive changes)

  - sometimes surgery is done cosmetically just for involved bone, then replace bone flap with prosthetic cosmetically-acceptable flap; historically, attempts were to boil bone flap in OR while removing meningioma (autoclaving is worse – destroys cells and bone matrix)
  - remove bone flap → intraoperative bone flap irradiation (e.g. 100 Gy)
  - if there is more affected bone – drill it off with diamond drill bit (useful to have CT loaded for navigation).

### VERY LARGE MENINGIOMA

- consider preoperative embolization (space closely with resective surgery as tumor recruits new vessels very fast, plus, tumor swells due to necrosis and patient may deteriorate).

- tumor might be invading brain cortex – better to debulk (make cruciate durotomy over tumor center to start debulking) but leave tiny rim of tumor on cortex → postop radiation (it will take long time until tumor grows back to fill original volume again).

### OLFACTORY GROOVE MENINGIOMA

A. Transnasal endoscopic resection – for small tumors. See p. Op300>

B. (Unilateral*) Subfrontal craniotomy ± orbital osteotomy

C. Frontal interhemispheric approach (ligating anterior portion of superior sagittal sinus)

- tumor arterial supply and perforator arteries to hypothalamus must be differentiated because both arise from anterior circulation.

- these tumors receive their blood supply through various sources:
  1. ethmoidal arteries (branches of ophthalmic arteries)
  2. branches from middle meningeal artery
  3. carotid arteries.

- to avoid undue retraction of frontal lobes, these tumors are best approached through low frontal craniotomy entering frontal sinus (up to removing suprorbital rim).

- to allow adequate visualization, falx should be completely sectioned after 2-0 silk suture ligating most anterior aspect of SSS.

- these tumors often invade ethmoid sinuses and, at times, sphenoid sinus.
• Care should be taken to identify and preserve both optic nerves. Note that usual relationship between optic nerves and carotid arteries might not hold true owing to displacement of these vital structures by tumor.

**TUBERCULUM SELLAE / ANTERIOR CLINOID REGION MENINGIOMAS**

• Preoperative imaging of clinooid region meningiomas can accurately predict the presence or absence of tumor involvement of the clinoiod in only 75% of cases. In light of the fact that a quarter of patients with radiographically negative clinooids will have tumor present on pathological analysis, recommend a clinoidectomy for all clinoiid region meningiomas.

Endoscopic approach:

Lateral see-through illustration of a typical meningioma of the tuberculum sellae. The extent of bone removal underlying the typical dural attachment is highlighted in blue. Note the anterior extension along the planum sphenoidale and the inferior extension into the sella turcica. Inset: Superolateral view demonstrating the typical planum attachment, optical canal invasion, and displacement of the optic apparatus and surrounding vasculature.

Upper: Anterior endoscopic view of the posterior wall of the sphenoid sinus after removal of the mucosa revealing the relevant bony anatomy. Note the anterior sellar wall centrally, bilateral opticocarotid recesses laterally, and the suprasellar notch superiorly. The area of bone removal is shaded and outlined. Lower: Lateral view demonstrating superolateral extent of bone removal and trajectory of endoscope and high-speed drill.

**CONVEXITY MENINGIOMA**

• Although large tumor, presents little problem in removal.
• Large bone flap is made around tumor, dural incision circumscribes tumor, and dura attached to tumor is used to retract tumor from brain as microdissection frees adhesions between tumor and surrounding brain.
in dealing with convexity tumor invading dura and cranium, elevation of bone flap in usual manner may damage underlying brain. One plan is to form free flap of bone immediately adjacent to tumor, separated from larger second flap that encompasses entire area. The second flap may be elevated to expose dura surrounding tumor and invaded dura and bone. The tumor may be separated from brain by careful dissection of arachnoid and separation of tumor from brain, preferably using magnification. The brain should be protected by cottonoid or Telfa strips.

- Invaded bone may be discarded. If invasion involves inner table only, this may be removed by burring. If removal is more extensive, bone flap may be autoclaved and replaced. A defect left by discarded flap may be corrected by prosthesis at same, or at later, operation.

- opening scalp and skull may be bloody because of hyper trophy of blood vessels originating from external circulation.

- dural blood vessels should be coagulated before opening dura to decrease tumor vascularity.

- usually tumor is separated from underlying brain parenchyma by arachnoid layer. This layer may not be complete at depth of tumor. In this location, separating tumor from brain may be difficult. Unless tumor is small and can be removed in one piece, best strategy for excising convexity meningiomas is to find arachnoid plane and dissect it gently.

- placing patties circumferentially around tumor allows quick identification of this crucial plane at later time.

- coagulate surface of tumor, then core it and invaginate outer layer to allow further circumferential dissection.

- pressure from meningioma can produce marked atrophy of compressed and devitalized cortex; epilepsy may result. Removal of atrophic cortex using techniques ordinarily applied to seizure surgery should be considered.

- perform dural grafting.

---

**PARASAGITTAL / PARAFALCINE MENINGIOMA**

- foremost consideration in surgically treating parasagittal meningiomas is to decide what to do with SSS (MRV is not yet sensitive enough to confirm unequivocally complete occlusion of SSS; diagnostic test of choice is still endovascular angiography with late venous images to look for possible delayed filling of involved portion of SSS):
  a) If SSS is completely obliterated* by tumor, it can be ligated safely and excised. The surgeon should be careful not to injure veins that run anteriorly and posteriorly to tumor. These veins may provide crucial collateral circulation for venous drainage of cerebrum and should be preserved at all costs. *If SSS is occluded gradually by tumor, venous drainage will be diverted over time through paraganglial veins.
  b) If SSS is only partially involved, decision of whether to sacrifice it depends on involved segment.

- anterior third of SSS (i.e. anterior to central (rolandic) veins) can usually be sacrificed with impunity; middle third, sacrificed at times; and posterior third, never ligated. In this author's experience, SSS is never sacrificed beyond anterior third.

- some surgeons resort partially involved sinus and reconstruct it later (either with vein or prothetic graft).

- author's opinion is that explaining to patient that some tumor was left behind that may need further resection at later date is better than taking undue risk of neurological deficit by obliterating more of SSS.

N.B. recurrence – MRV – if SSS patent → radiosurgery (resection is contraindicated)

---

**Chinese classification** - stages of tumor invasion and the level of blood flow restriction within the SSS:

- type I: lesion attached to the outer surface of the sinus wall
- type II: tumor fragment inside the lateral recess
- type III: invasion of the ipsilateral wall
- type IV: invasion of the contralateral wall and roof
- type V: complete sinus occlusion with one wall free from invasion
- type VI: complete sinus occlusion with no wall free from invasion

---

**SPHENOID WING MENINGIOMA**

- sphenoid-wing meningiomas present either as pneumatic meningiomas or as globular masses.
- sphenoid ridge meningiomas vary in approach, depending on whether they occupy outer, middle, or inner third of sphenoid bone:
1) outer-third tumors can be problem purely of tumor mass, purely of massive temporal hypotension from encasement tumor invading bone, or compression of both. When it is present, tumor mass insinuates itself in sylvian tissue, and its removal through frontotemporal craniotomy is complicated by tumor's adhesion (on its medial aspect) to sylvian veins. Surgical cure is not possible.

2) middle-third tumors grow into both frontal and temporal fossa in globular fashion. The approach is through frontotemporal craniotomy, with base of tumor approached first to eliminate blood supply. Surgical cure is likely.

3) inner-third tumors arise from anterior clinical process and compress optic nerve and encase carotid and middle cerebral arteries. In addition, medial sphenoidal meningiomas can grow diffusely into cavernous sinus and optic canal. Only in those situations where tumor presents early because of optic nerve compression is total removal even feasible. Most commonly, complete resection is not possible, and surgeon stops when risk of surgery exceeds potential benefits.

- need pterional to fronto-temporo-sphenoidal craniotomy – see p. Op340
- removing zygoma and orbital rim allows wider exposure of sphenoid wing, middle cranial fossa, anterior cranial fossa, and anterior clinoid.
- expose temporal floor and sphenoid wing
- tumor capsule incision at where tumor comes to surface → debulk → dissect away from vessels.
- careful when bipolarizing dura on temporal floor – trigeminal ganglion underneath (sensory loss).

Cavernous Sinus Meningioma

http://www.neurosurgicalatlas.com/grand-roumd/resection-of-cavernous-sinus-meningiomas

- issue of meningiomas involving cavernous sinus is currently area of intense interest in neurosurgery. No one doubts that, in experienced hands, such meningiomas can be treated successfully.
- debate centers on 2 points: when to operate and how aggressive resection should be. The following opinion is personal reflection on matter, and diverging views may be found in literature.
- asymptomatic cavernous sinus meningiomas should not be operated but should be monitored carefully by means of repeated physical examination and serial MRI. Symptomatic patients in otherwise healthy patients should be resected by neurosurgeons who are trained for such procedures.
- before attempting to remove tumor, surgeon should first diminish its mass. Tumor mass insinuates itself in sylvian tissue, and its removal through frontotemporal approach is complicated by tumour involving cavernous sinus and optic canal. Only in those situations where tumor presents early because of optic nerve compression is total removal even feasible. Most commonly, complete resection is not possible, and surgeon stops when risk of surgery exceeds potential benefits.
- after removing zygoma and orbital rim allows wider exposure of sphenoid wing, middle cranial fossa, anterior cranial fossa, and anterior clinoid.
- expose temporal floor and sphenoid wing
- tumor capsule incision at where tumor comes to surface → debulk → dissect away from vessels.
- careful when bipolarizing dura on temporal floor – trigeminal ganglion underneath (sensory loss).

Petrous Apex Meningioma

- in acoustic neurinomas, facial nerve usually lies anterosuperiorly to tumor and is encountered late in surgery. This relationship is lost in cerebellopontine angle meningiomas, because facial nerve may lie along posterior tumor edge and can be injured early in surgery (unless care is taken to identify it).
- before attempting to remove tumor, surgeon should first diminish its blood supply by coagulating its supplying arteries from dura. To do so, interface of tumor and petrous bone should be followed.
- before operation, one should have definite opinion on anterior clinoid artery (which passes through cavernous sinus). Coagulating it to decrease tumor vascularity.
- surgeon should remember that multitude of processes may affect cavernous sinus and mimic meningioma, including sarcoidosis and infection/inflammation that lead to Tolosa-Hunt syndrome.

 Petrotyal and Petroclival Meningiomas

- although partial resection is relatively straightforward, complete resection remains daunting task.
- partial resection usually does not translate into any benefit for patient and only renders further surgery more difficult; therefore, every attempt should be made to complete resection. If surgery has to be interrupted for logistical reasons, second operation should be scheduled earliest possible opportunity.
- multitude of approaches has been devised for these tumors.
- traditional approaches such as suboccipital or subtotal are usually insufficient to allow complete removal.
- more extensive approaches, such as petrosal (Kawase) approach, are needed. This approach consists of combined supratentorial and infratentorial craniotomies, associated with simple mastoidectomy down to solid angle (i.e. bone encasing inner ear). After tentorium is split, petroclival meningioma can be visualized in its entirety.

Tentorial and Torcular Meningiomas

- tumor usually may be supplied by multitude of vessels that arise from tentorial base. These should be coagulated thoroughly before one attempts to remove tumor.
- major supply may be Youmans-Cassani artery, which arise from cavernous portion of carotid artery and runs posteriorly to supply tentorium.
- this artery is usually not apparent on normal angiograms but may be conspicuous in angiograms of meningeal tumors.
- definite attempt should be made at recognizing Bernasconi-Cassani artery during surgery and coagulating it to decrease tumor vascularity.
- meningiomas often grow in both infratentorial and supratentorial compartments and should be approached accordingly.
- studying preoperative angiogram is imperative in cases of torcular meningiomas to delineate patency of different sinuses and available collateral circulation. Removing these tumors completely is often impossible because of partial involvement of venous sinuses.
- adequate demonstrable patency of opposite lateral or sagittal sinus may permit resection of involved sinus. The size of sinuses, however, at times may permit reconstruction of sinus after removal of one wall from which tumor extends into sinus.

Anterior (AL) Intracranial Meningiomas

- middle third of the tentorial free margin: pteronial, subtemporal, and retrosigmoid approaches.

Posterior Median (PM) Infratentorial Meningioma

- posterior third of the tentorial free margin: occipital or supraoccipital infratentorial approaches.
